ABSTRACT
We present a transport protocol whose goal is to reduce power consumption without compromising delivery requirements of applications. To meet its goal of energy efficiency, our transport protocol (1) contains mechanisms to balance end-to-end vs. local retransmissions; (2) minimizes acknowledgment traffic using receiver regulated rate-based flow control combined with selected acknowledgements and in-network caching of packets; and (3) aggressively seeks to avoid any congestion-based packet loss. Within a recently developed ultra low-power multi-hop wireless network system, extensive simulations and experimental results demonstrate that our transport protocol meets its goal of preserving the energy efficiency of the underlying network.

1. INTRODUCTION
Motivation: Multi-hop wireless networks are plagued with unique challenges: contention for the wireless medium, time-varying topology due to the variable quality of links or mobility, and power constraints imposed by battery lifetimes. The focus of this paper is the last challenge: power constraints. We seek to minimize the usage of energy so as to extend the lifetime of both individual nodes and the network as a whole, while meeting the requirements of applications.

While energy efficiency has been recognized as a challenge for some time [37], until recently, very little progress has been made. In the past couple of years we have be-
metric to minimize: the total number of node transmissions for each packet, or each conversation.\footnote{This metric admittedly ignores energy costs for computation and memory in the nodes. The usual logic for ignoring these costs is that the radio consumes far more energy.} The problem is hard because very little is known about minimizing transmissions across multiple nodes. There is plenty of research work on minimizing transmissions end-to-end, especially limiting the number of acknowledgments sent, but almost nothing on intermediate transmissions. And the one key piece of work in the area, Ludwig’s work on the interaction of end-to-end and hop-by-hop retransmissions [22], gives a depressing result: namely in a world where one needs both end-to-end and hop-by-hop retransmissions, it is very easy to have the two transmission mechanisms interact to cause more, rather than less, total transmissions. Our transport protocol coordinates end-to-end and hop-by-hop retransmissions by allowing the ends of the connection to explicitly control the amount of local retransmission effort, based on application’s reliability requirement. JTP’s objective of minimizing the number of total transmissions is not only beneficial in energy-constrained networks, but in any wireless network since limiting the overall number of link-layer transmissions effectively increases the network-wide capacity.

Our Contribution: Our transport protocol mediates between an application’s need to share information of varying importance over the network, and the system’s goal of minimizing energy expenditure per successfully delivered bit. Given that JAVeLEN is the state of the art in energy conserving network systems, our protocol uses JAVeLEN as the underlying architecture and thus we will refer to it as JTP (JAVeLEN Transport Protocol). Although JTP is implemented to work within JAVeLEN, it is designed to operate within any wireless (or wireline) architecture that provides an interface for JTP to both, control the number of node retransmissions made by the media-access protocol, and get at least indication of the available capacity of the channel, and of the packet loss rate. JTP’s architecture strives to maximize the modularity of the system. Information is propagated through packet headers and all the necessary hop-by-hop operations are performed by a separate module that is used by the MAC.

In this paper, we present a summary of our design and the novel features of JTP as follows:

- To the best of our knowledge, JTP is the first multi-hop wireless end-to-end transport protocol designed to perform hop-by-hop soft-state operations to improve (goodput and energy) performance while preserving the end-to-end principle [28] (Section 2).

JTP employs mechanisms akin to the Dynamic Packet State [33]—using packet headers to prop-

- JTP exploits any energy-gain opportunities provided by the applications. Historically, transport protocols have offered a particular reliability/QoS model and the application’s task was to pick the transport protocol whose model most closely met the application’s needs (e.g. UDP, TCP, ITP [25], RTP [13]). JTP is designed to act as a “generic” transport protocol tailored by the application based on its specific QoS semantics. JTP uses the tolerance of the application to losses and limits the network’s effort in trying to deliver a packet, based on the packet’s individual importance as well as current energy costs (Section 3).

- In JTP, the receiver is fully responsible for controlling all transmission parameters; connection’s sending rate, retransmission requests for missing/lost packets, as well as the frequency of such controls. To the best of our knowledge, JTP is the first transport protocol that supports variable destination-controlled feedback trying to keep feedback as low as the stability and reliability of the network permits (Section 5).

- JTP implements a caching mechanism which enables intermediate nodes along the path of a JTP connection to temporarily store traversing packets.\footnote{We note that efficiency achieved by caching and repairing errors earlier using such in-network caching does not contradict the end-to-end argument of system design [28]—the source does not delete its copy of a packet until it gets an acknowledgment from the final destination that it has successfully received the packet. Furthermore, the soft-state nature of caches provides resilience to route changes.} This enables the recovery of lost packets as close to the receiver as possible. These pipelines of caches along paths generalize the single-level caching often employed in cellular-type (single wireless hop) networks [5]. Although a system that supports symmetric routes between hosts, like the JAVeLEN system, would exploit caching benefits to its fullest, the opportunistic design of the caching system would seize any chance for locally recovering lost packets, without interfering with the end-to-end semantics of each connection.

To allocate bandwidth fairly among flows in the presence of in-network caching and retransmissions, a JTP sender backs off its sending rate to account for “internal” retransmissions triggered from caches on its behalf (Section 4).

- JTP also employs a (congestion-avoidance) rate-based flow control—using ATM-like explicit rate
feedback from the network—in an attempt to eliminate energy wastage associated with congestion-induced packet drops.

- JTP is implemented as “shared code” that can be run either in simulation or on real radio nodes. Results from simulation and from a prototype of JAVeLEN radios (Section 6) confirm the premise of JTP in reducing the energy consumed per delivered bit.

2. JTP DESIGN

As we sought to design a protocol that minimizes the total number of node transmissions required to deliver application data, we chose to decompose that goal into three subgoals:

1. **Minimize end-to-end retransmissions.** Ludwig’s work showed that we needed to strike a balance between end-to-end (source) and local retransmissions. End-to-end retransmissions effectively waste all the energy already expended on getting the packet at least part way to the destination by the initial transmission. So, while occasional retransmissions from the source are required (e.g. due to intermediate node failure or topology changes), we sought to do everything we could to retransmit a lost packet from the farthest downstream, intermediate node along the packet’s path which had received the packet successfully.

2. **Minimize acknowledgments.** Acknowledgments are, often, pure overhead—they carry no application data. Yet, they consume roughly as much energy as a data transmission. So, consistent with reliability and other goals, we would like to minimize acknowledgments.

3. **Avoid congestion loss in the nodes.** By design, a classic TCP-like congestion control induces packet drops, since loss is the only sign of congestion. The energy expended by packets that are discarded, simply to signal congestion, is wasted. In a world where energy is the key metric, congestion control should consume less energy than what discarding a packet implies. Assuming that JTP is effective in only transmitting data when necessary, JTP aims to avoid congestion instead of controlling it.

The result of these goals was the JTP architecture shown in Figure 1. JTP uses rate-based transmission controlled by the destination. Intermediate wireless nodes report on their condition in data packet headers. A Path Monitor and Path Controller at the destination collect this path performance data and adjust data rates to avoid congestion. Intermediate nodes retransmit packets on a per hop basis, cache packets, and examine end-to-end acknowledgments. If an acknowledgment indicates a packet was lost further along the path, the node will retransmit this packet, thereby avoiding an end-to-end retransmission (a la the work of Balakrishnan et al. [5]). Based on this design, we next look at how JTP actually works.

Before we delve into the details of JTP, we provide a brief description of the JAVeLEN system. JAVeLEN deploys a TDMA MAC which orchestrates nodes’ transmissions by using pseudo-random schedules, providing collision-free access to the channel and allowing nodes to turn off their radios when they are not in use. Each node also keeps statistics about link transmissions and idle slots in order to provide estimates of the available transmission rate and of the packet loss rate on every link. JAVeLEN uses an energy conserving link-state routing algorithm [29], that provides each node with a local, possibly inaccurate, view of the network’s topology.

![Figure 1: Elements of JTP](image)

2.1 A Packet-based View of JTP

We begin by describing JTP in terms of packets—data and acknowledgment packets—and how they flow between source and destination. Figure 2 shows the packet format for JTP packets. While the JTP header, shown in Figure 2(a), is attached to all packets, the ACK header, shown in Figure 2(b), is optional and is included only in packets that carry feedback information. Note that this is an optimized version of JTP headers that only carry the necessary information. In our prototype implementation the JTP headers are slightly longer, mainly for debugging purposes.

2.1.1 Data Packets

Data packets travel from the source to the destination of a JTP connection. In JTP, data packets contain three novel fields: available rate, loss tolerance, and energy budget.

- **Available rate:** The available rate of a link, from a node to its neighbor, represents its current available transmission capacity—in a TDMA MAC, like the JAVeLEN MAC, that available rate is determined by the current rate of unused (idle) time slots during which the neighbor is awake for reception; in CSMA/CA networks, a method similar to [20] can be used to estimate the available bandwidth. At each node visited, a packet is stamped with the minimum available rate collected so far along the path of the JTP connection. As described
in Section 5, this available rate is used by the flow controller at the destination to update the sending rate of the source. Note that due to retransmissions that may be required to get the packet to the next hop, a packet may consume more than one MAC-level transmission slot. So the available rate value must be normalized by the average number of MAC-level transmissions. Ludwig [22] pointed out that allowing multiple MAC-level transmissions can increase packet delay and also reduce the effective bandwidth that an application perceives. As we will see later, by allowing applications to control the number of MAC-level transmissions per link, JTP effectively gives applications control over the delay and effective bandwidth on every link.

- **Loss tolerance**: A source node encodes the desired end-to-end loss tolerance in packet headers. Each node along the path pre-computes the maximum number of transmission attempts to the next hop, given the remaining length of the path (known from the node’s view of the topology) and packet’s loss tolerance. The packet is dropped if this pre-determined maximum number of local attempts is exceeded. As described in Section 3, before forwarding the packet, the node updates the loss tolerance field so any left-over attempts (from the pre-determined maximum number) do not get used downstream, thus reducing the variability in energy consumption across nodes along the path.

- **Energy budget**: The source initially assigns each packet an energy budget value based on the energy the network would typically expend to deliver the packet successfully. A packet is dropped whenever the energy used exceeds the energy budget of the packet. This approach provides an energy-conscious mechanism for dealing with routing loops (as opposed to the traditional hop-count TTL) and, as we elaborate later, in conjunction with the loss tolerance field, creates a sturdy way to manage the energy expenditure per packet.

The available rate field addresses the goal of avoiding congestion loss. Because JAVeLEN provides a practically collision-free MAC layer, if the JTP flow controller ensures that it does not drive the available rate to zero, congestion-induced losses are avoided.3

The energy budget and loss tolerance fields manage the expenditure of energy per packet. By limiting the effort of each node to successfully deliver a packet, the loss tolerance field bounds the total transmission energy spent by each node. The energy budget on the other hand, sets an upper bound on the energy that the whole network might expend to deliver a packet to the destination. The deadline field is used by real-time traffic, and although this is out of the scope of this paper, it is included for completeness.

### 2.1.2 Acknowledgment Packets

JTP ACK packets carry data acknowledgments, as well as transmission rate and energy budget information from the receiver to the sender. The rate at which ACKs are fed back to the sender is regulated by the receiver, based on the stability conditions of the path. For a stable path, a minimum feedback rate is determined by the application based on its requirements—for example, an application with a more stringent delay requirement would require a higher feedback rate to achieve a more timely recovery of missing data. A lower feedback rate, if tolerated by the application, allows JTP to aggregate ACK information in a single packet, thus reducing feedback load.

It is well known that rate-based flow control is vulnerable to the loss of feedback messages. As we elaborate in Section 5, JTP overcomes this problem by having the receiver inform the sender of its feedback rate. So if the sender does not get an ACK within the expected feedback delay, it backs off its transmission rate. Furthermore, short-term, and significant, variations in path’s conditions (available rate or energy used) would be detected by the path monitoring function at the receiver, thus triggering an early feedback.

In addition to reporting rate and energy information, an ACK packet carries both positive cumulative and negative selective acknowledgments. Each intermediate node on the path examines the SNACKs and retrans-

---

3Even if the underlying MAC does not provide collision-free access, JTP’s operation will not be affected, since collisions would only increase the link loss experienced by packets, thus increasing the number of link-layer retransmissions per packet and effectively reducing the measured available bandwidth, which in turn forces the sources to back off.
mits missing packets if these packets are in the intermediate node’s cache—if they are, the node appropriately modifies the ACK packet so the sender is explicitly informed of such in-network retransmissions done on its behalf (cf. Section 4). Caching, and acknowledgments, are discussed in more detail in Section 4.

2.2 JTP Components

As mentioned earlier in Section 1, although JTP is an end-to-end transport protocol, it also performs hop-by-hop operations to improve its performance. In order to alleviate the overhead of the hop-by-hop operations and increase the protocol’s efficiency, JTP is divided into two main components: the end-to-end JTP (eJTP) and the hop-by-hop (or, intermediate) JTP (iJTP).

2.2.1 End-to-end JTP

The functionalities of eJTP are further categorized into application-specific and network-specific modules. This modularity makes JTP a more versatile transport protocol. In this work, we focus on bulk data transfers over multi-hop wireless networks.

• The application-specific module of eJTP is responsible for fragmentation and reassembly of application’s data. Moreover, it expresses the QoS requirements (e.g. reliability level) to the network-specific module to influence in-network packet handling decisions, flow control, and retransmission requests only for those missing packets that are important to the application.

• The network-specific module manages all JTP connections and implements the path monitor and the (congestion-avoidance rate-based) controller of per-packet transmission parameters.

2.2.2 Hop-by-hop JTP

iJTP performs all the mid-path (intermediate) cache-related and soft-state operations. It manages the local cache of every node by ensuring that only valuable data packets are stored, data packets indicated in SNACKs are retransmitted, and cached data packets are evicted based on the selected caching policy.

Soft-state per-packet operations performed by iJTP at each node, include:

• Update the available rate field: iJTP is responsible for acquiring from the MAC layer an estimate of the available rate to every neighbor, as well as an estimate of the packet loss rate on that link. It uses this information to estimate the effective available rate to each neighbor. iJTP stumps each passing packet with the lowest effective available rate (throughput) observed thus far along the path.

• Update the loss tolerance field: Based on the loss tolerance carried in the packet’s header and the link’s estimated packet loss rate, iJTP sets the number of data transmission attempts on that link, as we elaborate in Section 3. The loss tolerance field is then updated to reflect its value for the remainder of the path.

Besides the fact that iJTP must process all JTP packets that pass through a node, the above described soft-state operations require the crafting of cross-layer interactions with the MAC layer. In order not to compromise the performance of a node, by redundant copying, context switching, and message passing between JTP and the MAC layer, we implemented iJTP as a separate loadable plug-in module of the MAC protocol. iJTP is invoked whenever a packet is received or about to be transmitted over the air interface.\(^4\)

Algorithms 1 and 2 present in pseudo-code the operations of iJTP, which is invoked exactly before the transmission (Algorithm 1) and exactly after the reception (Algorithm 2) of a packet from the physical layer.

3. ADJUSTABLE RELIABILITY FOR ENERGY CONSERVATION

Not all applications (e.g. voice, video, images [25]) require full reliability to perform well. Given reliability targets from applications (provided by the application module), and knowledge of packet loss rates (provided by the MAC layer\(^5\)), JTP adjusts the effort it puts into

\(^4\)Although within the JAVeLEN system, iJTP resides in the MAC, iJTP operations can be performed by eJTP using an overlay type of architecture.

\(^5\)The MAC layer keeps statistics about successful packet transmissions and estimates the average packet loss rate experienced over each link.
delivering each packet, seeking to expend only enough energy to deliver “needed” packets. Specifically, iJTP controls the number of node transmission attempts on a per packet basis. In JTP, the reliability level is expressed in terms of the loss tolerance percentage (e.g. 10% of packets can be lost) encoded in the header of each packet.

Let \( l_{e2c} \) be the end-to-end loss tolerance requested by the application. Let \( n_i, i \in [0, H] \) be the nodes on the path from the source \( n_0 \) to the destination \( n_H \), where \( H \) is the total number of links on the path. Let \( q_i, i \in [0, H - 1] \) denote the probability that a packet sent by node \( n_i \) will be successfully delivered to the next node \( n_{i+1} \). In order to satisfy the end-to-end loss tolerance of the application, the following equation should hold:

\[
l_{e2c} = 1 - \Pi_{i=0}^{H-1} q_i \tag{1}
\]

The value of \( q_i \) changes depending on the number of node transmission attempts indicated to the MAC by iJTP. Let \( p_i \) denote the probability that a single node transmission from \( n_i \) to \( n_{i+1} \) fails, and let \( M_i \) denote the total number of node transmission attempts requested for a packet on link \( (n_i, n_{i+1}) \). Then \( q_i = 1 - p_i^{M_i} \), from which we can compute \( M_i \) as:

\[
M_i = \max(1, \min(\frac{\log(1 - q_i)}{\log(p_i)}, \text{MAX\_ATTEMPTS})) \tag{2}
\]

where \text{MAX\_ATTEMPTS} is the maximum number of link transmissions that the MAC allows. The challenge is to dynamically adjust the values of \( M_i \) for each packet in a flow so as to satisfy the desired \( l_{e2c} \).

If the length of the path to the destination is known, the values for \( q_i \)'s can be directly computed from equation (1), and encoded in the headers of packets. However, in a network setting where the topological views at the nodes are typically not accurate, the path length is estimated based on a node’s current view. Therefore, JTP carries out the computation of \( q_i \)'s at each node, as the packet travels toward the destination, thus using increasingly more accurate views.

Let \( l_{ti} \) be the loss tolerance that is encoded in the packet when received by node \( n_i \). Let \( H_i \) be the number of links from \( n_i \) to the destination. Before the node transmits the packet to its next-hop, it updates the loss tolerance field as follows:

\[
\Pi_{j=i}^{i+H_i-1} q_j = 1 - l_{ti} \Rightarrow q_i \Pi_{j=i+1}^{i+H_i-1} q_j = 1 - l_{ti} \Rightarrow \quad l_{ti(i+1)} = 1 - \frac{1 - l_{ti}}{q_i} \tag{3}
\]

Although there are many different strategies that might be employed to compute \( q_i \) on each link—e.g. imposing higher successful delivery requirement on less loaded links or on nodes with higher available energy—in this paper we assume that JTP attempts to assign the same \( q_i = q \) for all the links. From Equation (1) we get:

\[
q = (1 - l_{ti})^{\frac{1}{H_i}} \tag{4}
\]

By dynamically adjusting the hop-by-hop success probability experienced by each packet, the end-to-end reliability requirements are met even if the topological views at different nodes are inconsistent, or the path changes. Moreover, by assigning a loss tolerance target to each individual packet, JTP enables the application to prioritize its packets (e.g. video frames of varying importance).

We tested JTP under different reliability levels. Three different levels are considered 0% \( (jtp_{0}) \), 10% \( (jtp_{10}) \) and 20% \( (jtp_{20}) \).

Figures 3(a) and (b) demonstrate that by neither overachieving (e.g. TCP-like full reliability for all), nor underachieving (e.g. UDP-like no reliability for all), JTP manages to save energy and still satisfies an application’s requirements, denoted by the horizontal dotted lines in Figure 3(b).\(^7\) (See Section 6 for simulation details.) Figure 3(c) shows the maximum number of node retransmissions set by iJTP for each packet at the third node along a 4-node path. Packets that request higher reliability are retransmitted more times by the link layer in cases when the link quality is not good enough, and thus JTP directly affects the amount of network’s effort in delivering each packet.\(^8\)

4. CACHING

JTP employs in-network caching of data packets to avoid end-to-end (source) retransmissions as much as possible.

\(^7\)The plot of the jtp_{20} is always above the application’s requirement since the aggregate loss rate of the path is below 20%.

\(^8\)The flow that corresponds to 0% loss tolerance is omitted from this plot since iJTP will always assign its packets the maximum number of node attempts.
possible. Caching can be viewed as a second line of defense if all MAC-level attempts fail; for example, due to a temporary excessive degradation in link quality. The destination may request any of these cached packets that it is missing, and are still needed by the application.

Upon receiving a traversing ACK packet, a node checks the Selective Negative ACK (SNACK) field to determine whether any packet(s) requested for retransmission exists in the node’s local cache. Requested packets found in the cache are forwarded downstream toward the destination.

Besides the SNACK field, an ACK packet header also contains a locally-recovered packets field, used to indicate which of the packets requested for retransmission have been already locally retransmitted by some node. Upstream nodes check this field to avoid multiple retransmissions of the same packets. When the source of the transfer receives an ACK, it will only retransmit packets that remain in the SNACK field.

If the cache of a node becomes full, to insert a newly arriving packet, the packet evicted from the cache is the least recently manipulated, i.e. Least Recently Used (LRU) policy. The motivation is that it is unlikely that those packets not recently requested for retransmission would be ever requested in the future. A detailed study of different cache replacement strategies is the subject of future work.

4.1 Analysis of In-network Caching Gain

In this subsection, we provide an analytic assessment of the benefits of caching.

- **JTP with caching:** In order to compute an upper bound on the gains achieved by caching, we assume a best-case scenario whereby cache sizes are infinite, and the path is symmetric, thus each lost packet will be recovered by the last downstream node which has successfully received it.

  We compute the expected total number of node transmissions, denoted by $E[T_{tot}^{JTP}]$. In the presence of in-network caching, each packet will effectively be retransmitted over each link for as many times as needed, until it is successfully delivered to the next node. If $p$ is the link loss probability, the expected number of node transmissions on a link $l$ follows a geometric distribution with mean $E[T_{l}^{JTP}] = \frac{1}{1-p}$.

  The expected total number of node transmissions required by JTP in order to deliver $k$ packets over $H$ hops is given by:

  $E[T_{tot}^{JTP}] = k \times H \times \frac{1}{1-p}$  \hspace{1cm} (5)

- **JTP without caching:** In the case of JTP with no in-network caching (henceforth denoted by JNC), over each link, the packet is transmitted, say, at most $n$ times. If its transmission still fails, then it must be retransmitted from the source.

  Denote by $S > k$, the random variable representing the total number of packets sent by the source until $k$ packets are successfully delivered at the destination, then $E[S] = \frac{1}{q_{e2e}}$, where $q_{e2e}$ is the end-to-end success probability.

  When a packet is received at a node, the average number of node transmissions that it triggers is:

  $E[T_{i}^{JNC}] = (1-p) + 2(1-p)p + \cdots + n(1-p)p^{n-1} + np^{n} = \frac{1-p^{n}}{1-p}$

  Given that the link success probability is $q = (1-p^{n})$, the probability that a packet makes it over $i$ links is $q^{i}$ \hspace{1cm} (6)

  which then triggers $E[T_{i}^{JNC}]$ node transmissions. Thus, the total number of node transmissions for JNC is given by:

  $E[T_{tot}^{JNC}] = \sum_{i=0}^{H-1} E[S] \times q^{i} \times E[T_{i}^{JNC}]$

  $= \frac{k(1-p^{n})(1-(1-p^{n})^{H})}{(1-p^{n})(1-p^{n})^{H}} \approx \frac{k \times H}{(1-p^{n})^{H-1}(1-p)}$  \hspace{1cm} (6)

  For $H = 1$, equation (6) degenerates to (5). Observe that the cost of JNC is $(1-p^{n})^{H-1}$ times higher than that of JTP.

  To confirm the energy gains of caching, we compare by simulation JTP and JNC in Figure 4. (See Section 6 for experimental details.) Figure 4(a) shows the energy expenditure per successfully delivered application bit. As expected, as the path between the source and the destination increases, the energy gains achieved by employing in-network caching also increase. Figure 4(b) shows the per-node energy consumption in a linear 7-node topology. Observe that JTP not only expends less total energy, as expected, but also distributes more fairly the energy expenditure among nodes in the path.

4.2 Fair In-network Caching
enabling mid-path nodes to retransmit packets on behalf of sources may cause a violation of sending rate compliance imposed by the destination of a transfer. For the sake of fairness and congestion control, the source node must incorporate in-network retransmissions in its sending rate calculations. To this end, JTP forces sources to back off in accordance to the extra traffic that is induced by in-network retransmissions. When an ACK packet is received, the source uses the locally-recovered packets field to adjust its sending rate. Let $r(t)$ be the rate indicated to the source by a received ACK at time $t$. Let $N$ be the number of packets locally recovered within the network, and let $s_j$, $j \in [1,N]$ be the sizes of these packets. The source computes an appropriate back-off period $t_b$ as follows:

$$t_b = \frac{\sum_{j=1}^{N} s_j}{r(t)}$$

Figure 5 shows the short- (top plots) and long- (bottom plots) term average of the packet reception rate (throughput) at the destination for two competing flows. (See Section 6 for simulation details.) Flow 1 does not request packet retransmissions (i.e. UDP-like flow), while flow 2 requires that all its packets be delivered and thus invoking the local recovery mechanism of the in-network caches. We observe in the right plots, spikes in the reception rate of flow 2 when it does not back off its sending rate to account for its additional in-network retransmissions—the unfairness introduced is more evident from the long-term average plots.

5. DESTINATION BASED CONTROL

5.1 Path Monitoring using Flip-flop Filtering

One design concept of JTP is to adaptively minimize the frequency at which the destination node informs the source of new transmission parameters, such as a new sending rate. To this end, the end-to-end component of JTP, eJTP, collects sample measurements of the state of the connection’s path, such as the minimum available rate over the links of the path. Let $x_i$ denote the $i^{th}$ sample of a path’s metric, $\bar{x}$ the estimated average, and $\bar{R}$ the estimated deviation from the average. We use principles from statistical quality control [23] to detect a significant change in the path’s state, which then triggers the destination to send additional feedback signal, in addition to feedback sent regularly at a low frequency.

To that end, we estimate the EWMA’s $\bar{x}$ and range $\bar{R}$ as follows:

$$\bar{x} = (1 - \alpha)x + \alpha x_i, \text{ initially } \bar{x} = x_0$$
$$\bar{R} = (1 - \beta)|x_i - x_{i-1}|, \text{ initially } \bar{R} = \frac{x_0}{2}$$

$\bar{R}$ is used to estimate the deviation around $\bar{x}$ and is calculated only from samples $x_i$ within the following upper and lower control limits:

$$UCL = \bar{x} + 3\frac{\bar{R}}{\sqrt{128}}, \quad LCL = \bar{x} - 3\frac{\bar{R}}{\sqrt{128}}$$

Under normal operation, stable EWMA filters are employed, i.e. the weights $\alpha$ and $\beta$ are small so short-term variations are filtered out. As long as $x_i$ lies within the control limits, the state of the connection’s path is considered stable and feedback is only reported to the source at low frequency, say every $T$ seconds. Otherwise, $x_i$ is considered an outlier. A certain number of consecutive outliers is used as indication of significant and persistent change in the state of the path, which would then trigger an immediate feedback to the source node. At this point, eJTP at the destination switches to an agile EWMA filter where a larger $\alpha$ value is used, so that $\bar{x}$ catches up with the actual value. Once $x_i$ falls back again within the control limits, eJTP at the destination switches back to the stable filter for this connection. This usage of both stable and agile filters is known as a Flip-flop Filter [6].

In our implementation, we set $T$ as a function of the sending rate and of the cache size used in the network. Specifically,

$$T = \max(T_{LowerBound, n \times \frac{1}{\text{SendingRate}}}); n \geq 1.$$ 

Notice that this ensures that the destination does not send feedback/SNACK messages at a rate higher than the sending rate. The value of $T_{LowerBound}$ is dependent on the size of in-network caches, since if packets requested for retransmission by a feedback message have already been evicted from the cache then the energy savings achieved by infrequent feedback messages have already been achieved.

The value of $T$ is used to set the sender’s timeout field in the JTP ACK header shown in Figure 2(b).
would be offset by the energy consumed by packets that have to be retransmitted from the source. If $C$ is the cache size—a configurable parameter of the network—and $RTT$ is the round-trip time for the connection then

$$T_{\text{lower bound}} \leq C \times \text{Sending Rate} - RTT$$

**Figure 6: The effect of cache size for various network sizes.**

Figure 6 shows the effect of cache size on the performance of JTP for different network sizes and feedback rates. In this experiment one JTP flow is started over linear networks. (See Section 6 for experimental details.) The figure depicts the number of source retransmissions for increasing cache sizes. We observe the sudden drop in the number of source retransmissions once the cache size is large enough to hold missing packets until they are requested for retransmission from the caches. Increasing the cache size further does not improve the performance significantly.

Figure 7 depicts the energy gains achieved by using variable-rate feedback instead of a constant rate. In this experiment, a linear topology of 8 nodes is used, with one long-lived flow competing with several short-lived flows. (See Section 6 for simulation details.) We vary the rate of constant-rate feedback—as expected, as the feedback rate increases, the total energy consumed (Figure 7(a)) increases since more feedback/ACK packets are generated; and for low feedback rates, we observe a high number of packet drops in the queues of intermediate nodes (Figure 7(b)) because the sender of the long-lived flow does not back off fast enough causing congestion in the system. Using variable-rate feedback, JTP not only achieves low energy consumption, but also minimizes packet drops in the system since whenever the system load increases, it sends a timely feedback forcing the sender to back off.

### 5.2 Congestion Avoidance Mechanism

When the flip-flop path monitor triggers a new feedback message, the path controller at the destination should set the transmission parameters (sending rate, energy budget), to be used by the source for the subsequent packets until a new feedback is received.

#### 5.2.1 PF/MD Sending Rate Controller

This controller at the destination sets the sending rate using the minimum available rate collected along the path of the JTP connection. Let $A$ denote the average available path rate measured at the eJTP destination, and $\delta \geq 0$ indicate the target available path rate. If $A > \delta$ then the source increases its sending rate $r$ in proportion to the current available capacity and, to improve fairness among competing flows, inversely proportional to the current sending rate:

$$r(t+1) = r(t) + K_I \frac{\bar{A}(t)}{r(t)}, \quad 0 < K_I < 1 \quad (9)$$

On the other hand, if there is little available rate ($\bar{A} < \delta$), then the source decreases its sending rate multiplicatively:

$$r(t+1) = K_D r(t), \quad 0 < K_D < 1 \quad (10)$$

We note that the eJTP destination also limits the sending rate by its delivery rate up the stack to the receiving-side of the application.

#### 5.2.2 Stability Analysis of PI$^2$/MD Rate Controller

In order to analyze the stability of the controller, consider a single JTP flow adapting its sending rate over a fixed-capacity channel. For analytical tractability, let’s ignore the EWMA computation of the available rate, that is, if $r(t) < C$, then the JTP source adapts its rate as follows:

$$r(t+1) = r(t) + K_I \times \frac{(C - r(t))}{r(t)} \quad (11)$$

On the other hand, if $r(t) > C$, then the JTP source adapts its rate as follows:

$$r(t+1) = K_D \times r(t) \quad (12)$$

Observe that the system remains non-linear, with two operating regions determined by whether the sending rate $r(t)$ is less than or greater than the capacity $C$. We next consider each of these two regions, and prove stability by showing that the value of a positive Lyapunov function $V(r)$ decreases with each iteration.
• $r(t) < C$ Region: Define $V(r) = C - r$. Then:

$$V(r(t + 1)) - V(r(t)) = (C - r(t + 1)) - (C - r(t)) =$$

$$C - (r(t) + K_I \times \frac{C - r(t)}{r(t)}) - (C - r(t))$$

$$= -K_I \times \frac{C}{r(t)} - 1 < 0$$

Thus, the only condition for $V(r)$ to decrease is that $K_I > 0$, regardless of the exact value of $K_I$. Of course, the exact value of $K_I$ determines the tradeoff between speed of convergence and quality of the steady-state behavior—a higher value of $K_I$ leads to faster convergence but higher oscillations.

• $r(t) > C$ Region: Define $V(r) = r - C$. Then:

$$V(r(t + 1)) - V(r(t)) = (r(t + 1) - C) - (r(t) - C) =$$

$$K_D \times r(t) - C - r(t) + C = -r(t) \times (1 - K_D) < 0$$

Observe that, for $V(r)$ to decrease, it is required that $K_D < 1$.

Thus, $K_I > 0$ and $K_D < 1$ are sufficient conditions for convergence. Furthermore, at steady-state as $t \to \infty$, substituting $r(t + 1) = r(t)$ in Equation (11), we have $r(t) \to C$, hence the rate control is efficient.

Observe that in the case of lower frequency of sending-rate update, the above analysis still applies, i.e. the system converges albeit at a slower pace.

5.2.3 $PF^2/MD$ Fairness under Dynamic Conditions

![Figure 8: Rate adaptation for two competing JTP flows.](image)

Figure 8 demonstrates the behavior of the flip-flop path monitor of a long-lived flow 1 when competing with a short-lived flow 2 which starts and ends at times 1000 and 1250, respectively. We observe (in the zoomed-in bottom plots) how the average value of available rate catches up with the instantaneous reported values as the monitor switches to the agile EWMA filter, so that the JTP source of flow 1 quickly backs off or increases its rate accordingly. The top plots show the fair convergence of flow rates when flow 2 is present.

5.2.4 Energy Budget Controller

Let $e_{UCL}(t)$ be the current upper control limit of the flip-flop path monitor for the energy consumption of individual packets. The energy budget $e$ that is reported back to the source is computed as follows:

$$e(t + 1) = \beta e_{UCL}(t), \ \beta > 1$$

(13)

where $\beta$ is a parameter defined by the application module that denotes the importance of each packet, since the energy budget controls the extra effort the network should invest in the delivery of each packet under transient surges in energy consumption, or in the case of route failures. $\beta$ should be greater than one so that the path monitor is able to detect outliers.

6. PERFORMANCE EVALUATION

Earlier in the paper, we have shown simulation results that demonstrate the operation and performance of the various mechanisms in JTP. In this section, we present additional results from the evaluation and testing of JTP.

JTP is written as “shared code” so it can run on any operating-system/hardware platform. To date, adaptation layers have been written to interface the shared code of JTP with either the OPNET simulation environment [1] or the Linux OS over JAVeLEN radios [11, 26]. We start by showing OPNET simulation results, then Linux testbed results.

6.1 Simulation Results

In order to thoroughly evaluate the performance of JTP, two types of topology are considered. Initially, JTP was tested on static linear topologies in order to study the effect of path length between sender and receiver on performance. We also evaluated JTP on random topologies, with and without mobility of nodes, to show its performance in realistic scenarios.

In order to provide a comprehensive and fair comparison against existing transport approaches for multi-hop wireless networks [9,21,34,41], JTP is compared against two representative protocols.

• TCP-SACK: TCP-SACK is chosen as a representative for all window-based approaches and as the most commonly implemented protocol in working systems. In order to have a more competitive performance, we use a rate-based flavor of TCP-SACK, whereby the rate of each flow is set by the well-known throughput equation of TCP [24]. Thus we remove artifacts from the window-induced burstiness of data and ACK streams, similar to what TCP pacing [2] does. Moreover, we used delayed ACKs (one ACK every two packets) in an attempt to reduce the rate of the ACK stream. The
SACK version helps TCP selectively retransmit lost packets only.

- **ATP-like:** In order to compare against the class of explicit rate-based transport protocols, we implemented a protocol which adjusts the sending rate based on explicit feedback collected by intermediate nodes, supports only end-to-end recovery, and has constant-rate feedback from the receiver. The feedback period is set to be larger than RTT as suggested for ATP [34]. ATP adjusts its sending rate based on explicit rate feedback from the path and thus takes into account real congestion capturing the behavior of TCP CLAMP [3].

  Given that TCP-SACK and ATP only support 100%-reliability transfers, we will consider only bulk transfers with 0% loss tolerance. Unless otherwise stated, the configuration parameters used throughout the experiments are listed in Table 1. In this prototype implementation the JTP header is 28 bytes and the JTP ACK header is 200 bytes.  

  In this paper, we show two different performance metrics to compare the efficiency of each protocol.

  - **Energy per delivered bit:** This measure captures the system-wide energy consumed to deliver each data bit to applications. Since our goal is to evaluate the energy consumption of transport protocols, we are only concerned with the energy actually spent to transfer packets of the transport layer, and thus we will not consider the energy consumed for network maintenance by the lower layers. To this end, a monitor is placed in the link layer that computes the energy spent for the transmission of each transport-layer packet based on the transmission power, the radio’s datarate and the packet’s length.

  - **Goodput:** This measure captures the total rate at which the network delivers new data to the applications, and therefore evaluates how efficient the network resources are utilized.

### 6.1 Static Linear Topologies

In these experiments the source and the destination of two competing flows are placed at the two ends of the network. To capture the varying quality of wireless links, the value of the average pathloss of each link alternates between a good state (low loss) and a bad state (high loss). Each link is in bad state approximately 10% of the time. The average duration of the bad period is 3 seconds. The results shown are the average of twenty (independent) runs along with 95% confidence intervals. Each simulation run lasted for 2500 seconds, and flows were started randomly after a warm-up period of 900 seconds.

Figure 9(a) shows the energy per delivered bit for each protocol, for varying network sizes. JTP significantly outperforms all the other protocols. As the path length increases, ATP ends up expending twice as much energy as JTP to deliver one bit, while TCP-SACK expends almost five times more energy for the delivery of each bit.

Figure 9(b) demonstrates that JTP not only provides great energy savings, but also achieves higher goodput. Without sacrificing system’s performance, JTP minimizes the amount of feedback control messages, which in a wireless network environment, effectively “steal” bandwidth from users’ data.

### 6.1.1 Random Topologies

We begin by testing JTP over static random topologies. Nodes are randomly distributed in a two-dimensional field. In order to avoid getting disconnected topologies, the field size is set to ensure that the network is connected with high probability. The source and destination nodes of 5 simultaneous flows are chosen randomly. The presented results are the average of 10 independent runs, of 4000s each both for the static and the mobile scenarios. Given that the placement of the nodes and flows are chosen at random, the system-wide performance might vary significantly. In order to meaningfully compare across different protocols, we ensured that all the protocols run under the same conditions in the same run.

Figures 10(a) and (b) show the energy per delivered bit and the goodput achieved by various protocols for varying network size. JTP outperforms both ATP and TCP in both metrics.

In the next set of experiments, we tested JTP’s performance in a mobile setting for a 15-node network. Each node moves within the field at various speeds (low: 0.1m/s, moderate: 1m/s, fast: 5m/s). We used the random way point mobility model in which each node chooses a random direction and moves in that direction for an average distance of 47m. There is an average pause of 100s between movements for each node.

The JTP header, and especially the ACK header is not optimized in this prototype implementation.
RELATED WORK

Extensive studies [14] have demonstrated the inadequacy of TCP to serve as a transport protocol in wireless environments. Enhancements have mainly focused on alleviating the effects of assuming that packet losses are only due to congestion.

**Proxy-based approaches:** Focus on hiding wireless losses from the TCP sender [4,5] by retransmitting from caches at the wireline-wireless boundary. Ludwig has shown that, if not designed carefully, end-to-end and in-network retransmissions, used together, can cause worse performance than either alone [22]. Energy conservation in multi-hop wireless networks led us to extend this concept to retransmissions from caches anywhere along the wireless path. As we showed in this paper, JTP gives the ends of the connection explicit control over the amount of local retransmission effort. In addition, redundant source retransmissions are avoided by explicitly informing the sender of local (cache) retransmissions done on its behalf.

**End-to-end approaches:** Attempt to identify the type of loss either explicitly such as ATCP [21], or implicitly such as WTCP [32]. Even perfect knowledge of the reason of packet loss (e.g. congestion-induced vs. transmission error) at the sender, often, does not improve throughput performance [6,19]. Moreover, these schemes suffer from the slow adaptation of TCP’s AIMD mechanism [16] to the fast changing conditions of wireless links. TCP-Westwood [8] addresses this problem by augmenting AIMD with an estimate of the available bandwidth measured based on the ACK reception rate. Other approaches tried to alleviate the effects of bursty TCP traffic by clamping the congestion window [3] or by pacing TCP packets [2]. Although these approaches significantly improve TCP performance they still rely on packet loss to identify congestion. Our JTP protocol is rate-based and avoids congestion altogether.

**Receiver-based control:** The sender centric approach of TCP requires frequent feedback which may cause congestion and force the sender to back off. A receiver centric flavor of TCP, such as RCP [15], has been proposed, however the rate of the backward ACK stream is not reduced. Our JTP protocol is also receiver-based, but the feedback rate is dynamically adjusted based on the stability and reliability conditions of the forward path.

**Rate-based flow control:** To ameliorate the ACK compression problem, rate-based protocols [10] have been proposed, whereby the available rate could be explicitly collected and fed back to the sender [34]. These solutions still use frequent constant-rate feedback which competes with data flows for resources. Our JTP protocol attempts to reduce the feedback rate constrained by the conditions and cache sizes on the forward path.

**Application-specific protocols:** Transport protocols cognizant of a certain application’s QoS requirements have been devised, such as RTP [13] and ITP [25]. Our JTP protocol further generalizes such proposals by enabling any application to not only influence the flow and error control mechanisms but also in-network decisions.

Figures 11(a) and (b) show the energy per delivered bit and the goodput achieved by the three protocols. Figure 11(c) presents the relation between end-to-end and locally recovered packets—the values presented are normalized by the total data delivered to the applications. This graph shows that even in mobile environments, where the path between two nodes is constantly changing, deploying local caches is beneficial—we observe in-network retransmissions which result in energy gains and better distribution of retransmission effort across nodes.
regarding the handling of its packets.

**Energy-conscious scheduling and routing:** In all aforementioned research, energy consumption has not been examined. Approaches have been proposed to monitor and even shape application’s data to turn on and off the network interface on end-nodes for the purpose of energy savings, while still satisfying the application’s requirements [18]. These monitoring techniques are hard to apply in multi-hop wireless networks, where each node is both, a router and an end-node.

In the context of proxy-based schemes, the tradeoff between throughput performance and energy costs (due to transmission power and error control) was analyzed in [7]. For multi-hop wireless networks, several power-aware MAC scheduling and routing protocols have been proposed [27,31,35,39]: JAVeLEN [11,26] builds on this body of prior work. We demonstrated in this paper, that even if network nodes are parsimonious in their use of energy (e.g. nodes turned off when there is no data to transmit or receive), an energy-aware transport protocol, such as JTP, can achieve greater energy gains by turning on the radios only when it is absolutely necessary. To this end, JTP minimizes control traffic and avoids data transmissions that are unnecessary for meeting given delivery requirements of applications.

**Sensor protocols:** Energy-aware transport protocols have been proposed in the realm of sensor networks, such as PSFQ [38]. Given the goal of one-to-many reliable delivery in such sensor network realm (e.g. to program the sensors), issues that arise in multi-hop wireless networks regarding the fair allocation of resources among flows and the reduction of in-network overhead have not been considered.

**Other wireline protocols:** Other protocols, proposed for wireline networks, such as SCTP [12] and XCP [17], suffer from inefficiencies similar to TCP when employed in multi-hop wireless environments.

8. CONCLUSIONS AND FUTURE WORK

We presented JTP, an energy-conscious transport protocol, that is rate-based receiver-oriented with variable feedback, coordinated in-network error recovery, and application-aware per packet handling. Our results show that JTP outperforms traditional transport protocols (TCP and UDP) and a representative multi-hop wire-less transport protocol (ATP) in every respect. For all network sizes and mobility settings evaluated, JTP consistently provided higher goodput and consumed less energy per node and over the entire network.

Our research also contributes in the form of lessons learned. For example, we have demonstrated the need to have multi-level error recovery, via the MAC and caching, that is explicitly controlled by the ends of connections. This shows that problems in energy-awareness can yield non-intuitive solutions.

JTP provides a fresh perspective that offers many opportunities for future work. We are currently investigating energy-awareness in cache/memory management, and the support of other applications such as data collection and image transfers.
